1 Introduction

Strongly correlated transition-metal oxides have shown interesting physical properties. In this class, high valence-metal compounds, such as SrFeO$_3$ have attracted great attention due to their rich and anomalous physical properties. The recent success of the fabrication of BaFeO$_3$ thin films showed the large saturation magnetization (in-plane; 3.2 $\mu$B/f.u., out-of-plane; 2.8 $\mu$B/f.u.) in ferromagnetic-insulating phases with the lattice constant of 3.97 Å in a cubic crystal structure [1]. The origin of the highly insulating properties, however, had not yet been clarified. The spectroscopic studies of the electronic and magnetic structure would be invaluable to reveal the mechanisms. To achieve the purpose we performed Fe 2$p$ and O 1$s$ edge soft x-ray absorption spectroscopy (XAS) and x-ray magnetic circular dichroism (XMCD). The obtained results were analyzed by configuration-interaction cluster-model calculations. We clarified that the ground state were dominated by the $d^5$ configuration ($L_e$; ligand hole) rather than the $d^4$ configuration due to the negative charge transfer energy resulting in the presence the substantial magnetic moment even in oxygen sites. We also clarified the unusual insulating phase in BaFeO$_3$ thin films in the negative charge transfer energy derives from the significant stabilization of its ground state via the strong Fe 3$d$ - O 2$p$ hybridization.

2 Experiment and calculation

A single crystalline, cubic, fully oxidized 50 nm thin film of BaFeO$_3$ (with lattice parameter 3.97 Å) was grown on SrTiO$_3$ (001) substrate, using pulsed laser deposition. The details of fabrication are described in Ref. [1]. XAS and XMCD were carried out at BL-16A in Photon Factory at a temperature of 20 K. The magnetic of ~ 1 T was applied perpendicular to the thin film surface, strong enough to saturate the out-of-plane magnetization. XMCD was measured by under fixed circular polarization of the incident beam incident on the sample perpendicular to its plane. The XAS and XMCD spectra were collected with the total-electron-yield mode with the probing depth of ~ 20 Å [2]. The obtained results were analyzed by configuration interaction cluster-model calculations. The cluster-model calculations are one of the most suitable methods to analyze the those core-level spectra. In this model calculations we consider the electronic structure of Fe$^{4+}$ ion surrounded by 8 O$^{2-}$ ions octahedrally including the charge transfer effect from oxygen sites to iron site. The parameters to be fitted were the charge transfer energy from the O 2$p$ orbitals to the empty Fe 3$d$ orbitals.
Here, we assumed that the x-ray attenuation length at the saturation effect in total-electron-yield mode [2].

The coefficient of 1/0.58 for $M_{\text{spin}}$ due to strong electronic correlations [8]. Corrections of 1/0.88 for $M_{\text{spin}}$ and 1/0.49 for $M_{\text{orbital}}$ were also considered to compensate for the saturation effect in total-electron-yield mode [2].

Here, we assumed that the x-ray attenuation length at the saturation effect in total-electron-yield mode [2]. Since both the $M_{\text{spin}}$ (>0) and $M_{\text{orbital}}$ (>0) have the same sign in BaFeO$_3$, it suggests the substantial weight of the $d^nL$ configuration due to the negative charge transfer energy. The XMCD result gave a smaller $M_{\text{orbital}}$ than the value obtained by magnetization measurement [1]. The cause of the deviation is not clear at this moment, but there is a possibility that the magnetic moment on the oxygen site might cause the underestimation based on the total magnetic moment in the iron site.

In Fig. 2, the calculated Fe 2$p$ edge XAS (top) and XMCD (bottom) spectra are presented. The spectrum reproduces the features of the experimental results very well, unlike the atomic multiplet calculation for $d^7$ in Ref.[4], suggesting the importance of charge transfer effects in those systems.

The Fe 2$p$ edge XAS (top) and XMCD (bottom) spectra are shown in Fig. 1. The broad XAS 2$p_{3/2,1/2}$ peaks without shoulder structures reflects the heavily mixed state due to the strong hybridization in BaFeO$_3$ which is quite similar to that in SrFeO$_3$, and also suggests that the valence of Fe is not $3^+$ but $4^+$ [4]. XMCD shows a large peak intensity of $\sim 18\%$ of the XAS peak intensity. The XMCD intensity of BaFeO$_3$ thin film is approximately twice as large as that of bulk BaFeO$_3$ [5]. The orbital moment ($M_{\text{orbital}}$) and spin moment ($M_{\text{spin}}$), we applied sum-rule analysis [6, 7]. By applying the sum-rule analysis, we obtained a large magnetic moment of $M_{\text{orbital}} = 2.1 \pm 0.3 \mu_B$/f.u., com-posed of $M_{3\text{g}} = 1.8 \pm 0.2 \mu_B$/f.u. and $M_{\text{orbital}} = 0.3 \pm 0.1 \mu_B$/f.u. Note that we considered the correction coefficient of 1/0.58 for $M_{3\text{g}}$ due to strong electronic correlations [8]. Corrections of 1/0.88 for $M_{3\text{g}}$ and 1/0.49 for $M_{\text{orbital}}$ were also considered to compensate for the saturation effect in total-electron-yield mode [2].

Here, we assumed that the x-ray attenuation length at the 2$p_{3/2,1/2}$ edge is $\sim 200$ Å [2]. Since both the $M_{\text{spin}}$ (>0) and $M_{\text{orbital}}$ (>0) have the same sign in BaFeO$_3$, it suggests the substantial weight of the $d^nL$ configuration due to the negative charge transfer energy. The XMCD result gave a smaller $M_{\text{orbital}}$ than the value obtained by magnetization measurement [1]. The cause of the deviation is not clear at this moment, but there is a possibility that the magnetic moment on the oxygen site might cause the underestimation based on the total magnetic moment in the iron site.

In Fig. 2, the calculated Fe 2$p$ edge XAS (top) and XMCD (bottom) spectra are presented. The spectrum reproduces the features of the experimental results very well, unlike the atomic multiplet calculation for $d^7$ in Ref.[4], suggesting the importance of charge transfer effects in those systems.

The O 1$s$ edge XAS (top) and XMCD (bottom) spectra are presented in Fig. 3. The inset in the top panel shows the expanded XAS spectrum around the main peak. O 1$s$ edge XAS spectra of correlated compounds originate from transitions into unoccupied states with O 2$p$ character hybridized with transition metal 3$d$ states. There-fore, the structure of the spectrum is qualitatively related to empty bands of primarily Fe 3$d$ weight. The structure from 528 eV to 534 eV, mainly Fe 3$d$-related, is similar to that of SrFeO$_3$[4]. The O 1$s$ edge XAS of La$_{1-x}$Sr$_x$FeO$_3$ spectrum shows that a new structure below the threshold of LaFeO$_3$ grows rapidly with increasing Sr, and dominates the spectra at high concentrations, corresponding to the Fe related main structure in our spectrum. These features seen in SrFeO$_3$ and BaFeO$_3$ are attributed to an effective state created by strong Fe 3$d$ - O 2$p$ hybridization. Such effective states are also seen in La$_{1-x}$Sr$_x$CuO$_3$ and Li$_x$Ni$_{1-x}$O due to the anomalously strong antiferromagnetic coupling between Cu or Ni 3$d$ and O 2$p$ [9, 10]. The O 1$s$ edge XMCD spectrum directly shows that the effective state in BaFeO$_3$ has heavily O 2$p$ character with the peak intensity of $\sim 4\%$ versus that of XAS. This is the evidence for significant O 2$p$ hole character in the ground state due to the negative charge transfer energy and strong Fe 3$d$ - O 2$p$ hybridization.
The energy position of the XMCD peak, which is lowered by 400 meV from that of XAS, corresponds to the shoulder structure in XAS assigned by \( \epsilon_+ \) as shown in the inset. Since the threshold of XAS is dominated by the transition of \( \epsilon L \rightarrow 1s\delta \), the strong intensity of XMCD was observed at the XAS structure of the lowest energy even in the usually non-magnetic oxygen. Here, \( 1s \) denotes the O \( 1s \) core-hole created by the incident x-ray. Thus, when an extra electron is added to the ground state, the electron will be introduced into the ligand hole at the affinity level. By considering Hund's rule, the net spin moment of O \( 2p \) is parallel to that of Fe \( 3d \), because the XMCD spectra showed that their orbital moments are parallel. Since there is no spin-orbit interaction in the O \( 1s \) core-hole, O \( 1s \) edge XMCD just shows not spin moment but orbital moment in the O \( 2p \) orbital. The oxygen hole usually antiferromagnetically couples to the net spin on the iron site due to the \( p - d \) exchange interaction, which is consistent with the experimental oxygen \( 1s \) edge XMCD.

The ground states dominated by the \( dL \) configurations and the presence of the effective states in the final state of O \( 1s \) XAS spectrum strongly suggest the origins of the insulating properties in BaFeO\(_3\), thin films are the high covalency between Fe \( 3d \) – O \( 2p \) state, often called as covalent insulator [11]. If the ground states are dominated by the configurations including ligand holes, the compounds can be expected to be metallic due to the continuum state in the ground state. If the hybridization between transition metal \( 3d \) – O \( 2p \) is strong, the discreet state would be generated under the continuum state. As a result, the compounds would show the insulating properties. In the case of the hole doped high \( T_c \) superconducting copper oxides, the discreet states are often called as Zhang-Rice singlet state. NaCuO\(_2\) has an insulating properties due to the ground state including of the discreet state generated by the strong hybridization between Cu \( 3d \) – O \( 2p \) corresponding to the Zhang-Rice singlet state [12]. In the case of the perovskite structure, those discreet states in a single cluster are expected to be strongly hybridized between each site and often collapses the band gap in a crystal. The lattice constant of BaFeO\(_3\), however, is so large that the hybridization between sites is greatly reduce. As a result the band gap is remained to open in BaFeO\(_3\), thin films.

4 Conclusion

We performed Fe \( 2p \) and O \( 1s \) edge XAS and XMCD measurements to clarify the electronic structure of BaFeO\(_3\). We clarified the valence of Fe in BaFeO\(_3\) is Fe\(^{+} \) by Fe \( 2p \) edge XAS and it has large saturation magnetic moment of 2.1\( \mu_B/\text{f.u.} \) by Fe \( 2p \) edge XMCD. Those spectra were well reproduced by the cluster-model calculations with negative charge transfer energy. O \( 1s \) edge XAS revealed the presence of the effective state in BaFeO\(_3\) due to the strong Fe \( 3d \) – O \( 2p \) hybridization which has substantial magnetic moment due to the oxygen holes in the ground state of BaFeO\(_3\), thin films. Those results were suggested that the mechanism of the insulating properties in BaFeO\(_3\) is strong Fe \( 3d \) – O \( 2p \) hybridization under the negative charge transfer energy and classified as a covalent insulator.
